

# Heaps

## Recall Priority Queue ADT

- A priority queue stores a collection of entries
- Typically, an **entry** is a pair (key, value), where the **key** indicates the priority
- Main methods of the Priority Queue ADT
  - **insert**(e) inserts an entry e
  - **removeMin**() removes the entry with smallest key
- Additional methods
  - **min**() returns, but does not remove, an entry with smallest key
  - **size**(), **empty**()
- Applications:
  - Standby flyers
  - Auctions
  - Stock market

## Recall PQ Sorting

- We use a priority queue
  - Insert the elements with a series of **insert** operations
  - Remove the elements in sorted order with a series of **removeMin** operations
- The running time depends on the priority queue implementation:
  - Unsorted sequence gives selection-sort:  $O(n^2)$  time
  - Sorted sequence gives insertion-sort:  $O(n^2)$  time
- Can we do better?

### Algorithm **PQ-Sort**( $S, C$ )

**Input** sequence  $S$ , comparator  $C$  for the elements of  $S$

**Output** sequence  $S$  sorted in increasing order according to  $C$

$P \leftarrow$  priority queue with comparator  $C$

**while**  $\neg S.empty()$

$e \leftarrow S.front(); S.eraseFront()$

$P.insert(e, \emptyset)$

**while**  $\neg P.empty()$

$e \leftarrow P.removeMin()$

$S.insertBack(e)$

## Heaps

- A heap is a binary tree storing keys at its nodes and satisfying the following properties:
- **Heap-Order**: for every internal node  $v$  other than the root,  $key(v) \geq key(parent(v))$
- **Complete Binary Tree**: let  $h$  be the height of the heap
  - for  $i = 0, \dots, h - 1$ , there are  $2^i$  nodes of depth  $i$
  - at depth  $h - 1$ , the internal nodes are to the left of the external nodes
- The **last node** of a heap is the rightmost node of maximum depth

# Height of a Heap

- Theorem:** A heap storing  $n$  keys has height  $O(\log n)$

Proof: (we apply the complete binary tree property)

- Let  $h$  be the height of a heap storing  $n$  keys
- Since there are  $2^i$  keys at depth  $i = 0, \dots, h-1$  and at least one key at depth  $h$ , we have  $n \geq 1 + 2 + 4 + \dots + 2^{h-1} + 1$
- Thus,  $n \geq 2^h$ , i.e.,  $h \leq \log n$

# Heaps and Priority Queues

- We can use a heap to implement a priority queue
- We store a (key, element) item at each internal node
- We keep track of the position of the last node

# Insertion into a Heap

- Method `insertItem` of the priority queue ADT corresponds to the insertion of a key  $k$  to the heap
- The insertion algorithm consists of three steps
  - Find the insertion node  $z$  (the new last node)
  - Store  $k$  at  $z$
  - Restore the heap-order property (discussed next)

# Upheap

- After the insertion of a new key  $k$ , the heap-order property may be violated
- Algorithm `upheap` restores the heap-order property by swapping  $k$  along an upward path from the insertion node
- `Upheap` terminates when the key  $k$  reaches the root or a node whose parent has a key smaller than or equal to  $k$
- Since a heap has height  $O(\log n)$ , `upheap` runs in  $O(\log n)$  time

## Removal from a Heap (§ 7.3.3)

- Method `removeMin` of the priority queue ADT corresponds to the removal of the root key from the heap
- The removal algorithm consists of three steps
  - Replace the root key with the key of the last node  $w$
  - Remove  $w$
  - Restore the heap-order property (discussed next)

## Downheap

- After replacing the root key with the key  $k$  of the last node, the heap-order property may be violated
- Algorithm `downheap` restores the heap-order property by swapping key  $k$  along a downward path from the root
- Upheap terminates when key  $k$  reaches a leaf or a node whose children have keys greater than or equal to  $k$
- Since a heap has height  $O(\log n)$ , `downheap` runs in  $O(\log n)$  time

## Updating the Last Node

- The insertion node can be found by traversing a path of  $O(\log n)$  nodes
  - Go up until a left child or the root is reached
  - If a left child is reached, go to the right child
  - Go down left until a leaf is reached
- Similar algorithm for updating the last node after a removal

## Heap-Sort

- Consider a priority queue with  $n$  items implemented by means of a heap
  - the space used is  $O(n)$
  - methods `insert` and `removeMin` take  $O(\log n)$  time
  - methods `size`, `empty`, and `min` take time  $O(1)$  time
- Using a heap-based priority queue, we can sort a sequence of  $n$  elements in  $O(n \log n)$  time
- The resulting algorithm is called heap-sort
- Heap-sort is much faster than quadratic sorting algorithms, such as insertion-sort and selection-sort

# Vector-based Heap Implementation

- We can represent a heap with  $n$  keys by means of a vector of length  $n + 1$
- For the node at rank  $i$ 
  - the left child is at rank  $2i$
  - the right child is at rank  $2i + 1$
- Links between nodes are not explicitly stored
- The cell of at rank 0 is not used
- Operation insert corresponds to inserting at rank  $n + 1$
- Operation removeMin corresponds to removing at rank  $n$
- Yields in-place heap-sort

# Merging Two Heaps

- We are given two two heaps and a key  $k$
- We create a new heap with the root node storing  $k$  and with the two heaps as subtrees
- We perform downheap to restore the heap-order property

# Bottom-up Heap Construction

- We can construct a heap storing  $n$  given keys in using a bottom-up construction with  $\log n$  phases
- In phase  $i$ , pairs of heaps with  $2^i - 1$  keys are merged into heaps with  $2^{i+1} - 1$  keys

# Example

## Example (contd.)

## Example (contd.)

## Example (end)

## Analysis

- We visualize the worst-case time of a downheap with a proxy path that goes first right and then repeatedly goes left until the bottom of the heap (this path may differ from the actual downheap path)
- Since each node is traversed by at most two proxy paths, the total number of nodes of the proxy paths is  $O(n)$
- Thus, bottom-up heap construction runs in  $O(n)$  time
- Bottom-up heap construction is faster than  $n$  successive insertions and speeds up the first phase of heap-sort
